

L25 SOUND IN MEDICINE**Density, pressure and disturbance:-**

The compressions and rarefactions can also be described by density changes and by displacement of atoms and molecules from their equilibrium positions

When compression takes place in the medium, the density and pressure of the medium increase.

When rarefaction takes place in the medium, density and pressure of the medium decrease.

This increase and decrease in density and pressure are temporary.

Thus, compression is called the region of high density and pressure.

Rarefaction is called the region of low density and pressure.

Energy is carried by the wave as potential and kinetic energy. The intensity I of sound wave energy passing through $1 \text{ m}^2/\text{s}$. Or watts per square meter for plane wave I is given by :

$$I = \frac{1}{2} \rho V A^2 (2\pi f)^2 = \frac{1}{2} Z (AW)^2$$

where ρ : is the density of the medium

V : is the velocity of sound

f : is the frequency

W : is the angular frequency which equals $2\pi f$

A : is the maximum displacement amplitude of atoms from equilibrium position

Z : is the acoustic impedance.

Impedance is the relationship between acoustic pressure and the speed of particle vibration.

Equal to density of a medium multiplied by propagation speed. Impedance units are rayls.

$$Z = \rho_0 c$$

Note: Density increases, impedance increases

Propagation speed increases, impedance increases

The intensity can also be expressed as

$$I = (P_0)^2 / 2Z$$

Where, P_0 is the maximum change in pressure.

Interaction of sound wave with tissue

When a sound wave hits the body, part of the wave reflected and part transmitted into the body.

R : is the reflected pressure amplitude

A_0 : is the incident pressure amplitude

Perpendicular incidence.

The impedances of the two media at the boundary determine the strengths of the reflected and transmitted pulses.

The ratio of R/A_0 depends on acoustic impedance of the two media, Z_1 and Z_2
The relationship is

$$\frac{R}{A_0} = \frac{Z_2 - Z_1}{Z_2 + Z_1}$$

Intensity reflection coefficient:

$$\text{IRC} = \left(\frac{Z_2 - Z_1}{Z_2 + Z_1} \right)^2$$

Note: Difference between impedances increases, IRC decreases.

For a sound wave in air hitting the body, Z_1 is the acoustic impedance of air and Z_2 is the acoustic impedance of tissue.

If $Z_1 = Z_2$ There is no reflected wave and transmission to the sound medium is complete

If $Z_2 < Z_1$ The sign change indicates a phase change of reflected wave.

The ratio of the transmitted pressure amplitude T to the incident wave amplitude A_0 is

$$T/A_0 = 2Z_2 / (Z_1 + Z_2)$$

It is obvious that whenever acoustic impedances differ greatly there is almost complete reflection of sound intensity this is the reason heart sounds are poorly transmitted into the air adjacent to the chest.

Intensity transmission coefficient:

$$\text{ITC} = 1 - \text{IRC}$$

Perpendicular incidence

When a wave hits at an angle θ_1 (**not Perpendicular incidence**) to a boundary between two media

$$\sin \Theta_1 / V_1 = \sin \Theta_2 / V_2$$

V_1 and V_2 are the velocities of sound in two media, Θ_1 is the angle of the incident wave, Θ_2 is the angle of the refracted sound wave. Because sound can be refracted, acoustic lenses can be constructed to focus sound waves.

Example .2

Calculate the ratios of the pressure amplitudes and intensities of the reflected and transmitted sound waves from air to muscle.

$$\frac{R}{A_0} = \frac{1.64 \times 10^6 - 430}{1.64 \times 10^6 + 430} = 0.9995$$
$$\frac{T}{A_0} = \frac{2(1.64 \times 10^6)}{1.64 \times 10^6 + 430} = 1.9995$$

Also we obtain the ratios of the reflected and transmitted intensities

$$(R^2/2Z_1)/(A_0^2/2Z_1) = (R/A_0)^2 = (0.9995)^2 = 0.9990$$

$$(T^2/2Z_2) / (A_0^2/2Z_1) = (Z_1/Z_2)(T/A_0)^2 = 0.001$$

When the acoustic impedances of the two media are similar almost all of the sound is transmitted into the sound medium, choosing materials with similar acoustic impedance is called impedance matching. Getting sound energy into the body requires impedance matching.

Example.3

Calculate the amplitudes and intensities of the reflected and transmitted sound waves from water to muscle using the values from Table (في الكتاب المنهجي)

$$R/A_0 = (1.64 - 1.48) \times 10^6 / (1.64 + 1.48) \times 10^6 = 0.0513$$

$$T/A_0 = (1.64) \times 10^6 / (1.64 + 1.48) \times 10^6 = 1.0513$$

$$(R/A_0)^2 = (0.05013)^2 = 0.0026$$

$$Z_1/Z_2 (T/A_0)^2 = (1.48 \times 10^6 / 1.64 \times 10^6) (1.0513)^2 = 0.9974$$

Attenuation of sound wave

Weakening of sound as it propagates. When sound wave passes through tissue, there is some loss of energy due to frictional effects.

Attenuation includes absorption (conversion to heat), and reflection and scattering of the sound as it encounters tissue interfaces.

Absorption is the main factor that contributes to attenuation. Attenuation is quantified in decibels (dB).

The absorption of energy in the tissue causes a reduction in the amplitude of sound wave. The amplitude A at a depth X cm in medium is related to initial amplitude $A_0(x=0)$ by the exponential equation

$$A = A_0 e^{-\alpha x}$$

Where α is the absorption coefficient for the medium. (Attenuation coefficient)

Attenuation coefficient (alpha) is the attenuation that occurs with each cm the sound wave travels. The farther the sound travels the greater the attenuation.

Note: If attenuation coefficient increases, attenuation increases. If path length increases, attenuation increases

Attenuation increase with increasing frequency:

$$\text{Attenuation (dB)} = \alpha \times \text{frequency (MHz)} \times \text{path length (cm)}$$

Attenuation limits the depth of images (penetration).

Note: If frequency increases penetration decreases

Frequencies used in diagnostic ultrasound range from 2 to 15 MHz. Lower frequencies are used for deeper penetration.

✚ Since the intensity is proportional to the square of the amplitude, its dependence with depth is

$$I = I_0 e^{-2\alpha x}$$

Where I_0 is the incident intensity at $X = 0$ and I is intensity at a depth X ,

2α absorption coefficient. The half-value thickness (HVT) is the tissue thickness needed to decrease I_0 to $I_0/2$.

Example.4

What is the attenuation of sound intensity by 1 cm of bone at 0.8, 1.2 and 1.6 MHz?

- ❖ At 0.8 MHz, the HVT is 0.34 cm, there for 1 cm is about 3 HVT and intensity is reduced by 2^3 , or by factor 8 .
- ❖ At 1.2 MHz, the HVT is 0.21: 1 cm is nearly 5 HVT, and intensity is reduced by almost 2^5 , or by factor 32 .
- ❖ At 1.6 MHz, the HVT is 0.11 cm : 1 cm is about 9HVT, and intensity is reduced by 2^9 , or by factor of 512 .

❖ H.W1

- ❖ The sound intensity levels of 10^4W/m^2 can cause damage of the eardrum diaphragm. What is the displacement of the diaphragm at such intensity adopting an average frequency 1000Hz? Where the acoustic impedance for tissue equal $1.64 \times 10^4 \text{Kg/m}^2\text{s}$.

THE STETHOSCOPE

- ❖ The act of listening sounds with a stethoscope is called mediate auscultation or usually just auscultation.
- ❖ The main parts of a modern stethoscope are bell, which is either open or closed by a thin diaphragm, the tubing and the earpieces.

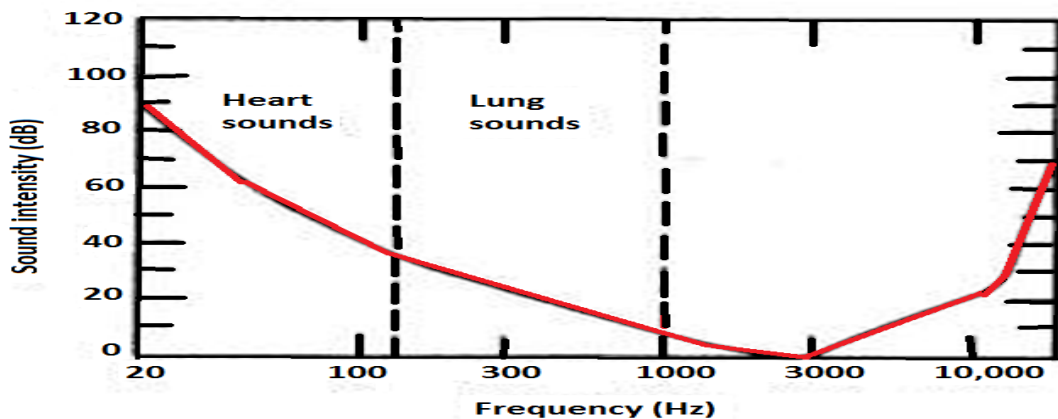

The open bell is an impedance matcher between the skin and the air and accumulates sounds from the contacted area. The skin under the open bell behaves like a diaphragm. The skin diaphragm has a natural resonant frequency at which it most effectively transmits sound; it is possible to enhance the sound range of interest by changing the bell size and varying the pressure of the bell against the skin and the skin tension.

A low frequency heart murmur will appear to go away if the stethoscope is pressed hard against the skin.

A closed bell is merely a bell with a diaphragm of known resonant frequency, usually high, that tunes out low frequency sound, its resonant frequency is controlled by the same factors that control the frequency of the open bell pressed against the skin.

The closed bell stethoscope is primarily used for listening to lung sounds, which are of higher frequency ranges of heart and lung sounds.

What is the best shape for the bell?

1-It is desirable to have a bell with as small a volume as possible.

The smaller the volume gas, the greater the pressure changes for given movement of the diaphragm at the end of the bell.

2-The volume of tubes should also be small. And there should be little frictional loss of sound to the walls of the tube.

Below about 100 Hz tube length does not greatly affect the efficiency. But above this frequency, decreases as the tube is lengthened.

At 200 Hz 15 dB is lost in changing from tube 7.5 cm long to tube 66 cm long. A compromise is a tube with a length of about 25 cm and diameter of 0.3 cm.
